1. Basics for anodization

1.1 What is anodization?

The formation of an oxide layer on aluminium or aluminium alloys by electrolyte baths is called anodization. When an oxide layer is formed on aluminium or on aluminium alloys by electrolyte baths, we speak of anodization. Aluminium forms very rapidly a thin oxide layer, about 0,1-0,5 µm, as soon as it is exposed to air. This natural layer protects the metal against further oxidation by oxygen, but cannot resist long against more aggressive conditions. To strengthen the protective effect of the layer and thereby cause the aluminium to become even more resistant to corrosion, anodization is applied.

This means that the oxide layer is increased up to 30 µm (0,3 mm) of thickness and is therefore about 8 times as hard as that of untreated aluminium. By the process of hard anodizing, even thicker layers can be achieved (> 100 µm). These generated anodized coatings are resistant against a large number of chemical compounds. Moreover, it is possible to embed colours into the porous layer, which gives a very pleasing look to the completed work piece. After the so-called sealing, these coloured layers are permanently bound to the oxide layer and cannot flake off easily (as, for example, varnishes often do).

1.2 Procedure/Process flow

To anodize an aluminium component with colours, you need to perform further steps apart from the actual anodizing (meaning the immersion of the work piece into the anodic electrolyte ), which are crucial for the end result. An overview of the entire process of the anodization is shown in the illustration below. You will find detailed information and instructions on how to proceed in each step in the following chapters of this manual.
1.3 Build-up of the anodic coating
During the actual anodic step, the aluminium work piece is connected to the positive pole and it oxidises because of the applied current flow. During this process the following chemical reactions happen:

- **Cathode:** $6\text{H}_3\text{O}^+ + 6\text{e}^- \rightarrow 3\text{H}_2 + 6\text{H}_2\text{O}$
- **Anode:** $2\text{Al} \rightarrow 2\text{Al}^{3+} + 6\text{e}^-$
- **Further reaction:** $2\text{Al}^{3+} + 9\text{H}_2\text{O} \rightarrow \text{Al}_2\text{O}_3 + 6\text{H}_3\text{O}^+$

The layer grows in capillary-like pores from the surface into the metal.
This means that the anodic coating is anchored directly in the original aluminium and can no longer be removed mechanically. These pores are able to absorb liquids, e. g. dyes, after the anodization process.

After a dye has been embedded into these pores, you can again close the oxide layer by the so-called sealing. This means that aluminium oxide reacts with water and crystallizes to hydrate alumina (Al2O3 x H2O) which clogs the pores.

The dye is thereby permanently bound to the aluminium and cannot be scraped off or flake like varnishes for example. It is of course also possible to not embed any dye or to seal the oxide layer directly after anodizing; then, the work piece keeps its silvery grey colour yet is nevertheless protected against corrosion.

1.4 What can be anodised?

In theory, every aluminium piece can be anodized. The result however is heavily depended on which kind of alloy was used. In principle, you can say that the purer the aluminium, the better the quality of the anodization. Still, pure aluminium is rarely used as material because of its softness. There are many alloys which can be anodised very well – you can find them in the following tables. These tables are divided into two main classes of aluminium alloys: wrought and casting alloys.
The wrought alloys are mainly used for rolling and extrusion pressing. Generally speaking, wrought alloys are more suitable for decorative anodization than casting alloys. The latter are used for example for sand casting and motor parts and others are produced in this way. For these alloys, the admixtures of alloy metal like, e.g. silicon and zinc, are very high and are therefore comparatively less suitable for anodization (although there are exceptions which work very well!).

Table 2: General view over the characteristics of the anodization of various commun casting alloys of aluminium.

It is important that the aluminium is not yet anodised. Otherwise, the work piece is no longer conductive and no further reaction can happen. For this purpose, the Tifoo De-Anodizer can be used (see chapter 4. Pre-treatment). Concerning accurately fitting aluminium parts, it must be noted that the after the anodization process, work piece will have increased in size.

We recommend using some aluminium test sheets for first anodization experiments to get a feel for the right approach.

2. SAFETY

While handling chemicals, several safety measures must be implemented so that yourself and others are not endangered. Make always sure to wear protection goggles and gloves. Furthermore, closed shoes and long clothes are important, old things are recommended, perhaps even an overall, if available. If you do come into contact with chemicals, you should immediately rinse the affected skin areas with clear water for several minutes. When clothing gets contaminated, change it as soon as possible.
In case of eye contact, remove contact lenses (if used) and consult your doctor immediately. On no account eat or drink the chemicals, nor should you eat or drink anything at or near your work place. For the baths used, especially the anodization bath and the De-Anodizer you should use additives of foam to suppress corrosive vapours. In case small quantities of vapours are released, they should not be inhaled. The working place should be well-aired and no fire may be lit in close proximity to it.

3. Tifoo Anodizing starter set
The starter set includes everything needed to achieve good first anodizing results without the need to buy further chemicals. It is suitable for beginners as well as more advanced users and covers the required basics.

The starter set includes:
- 1 x anodizing pre-treatment 1 litre
- 1 x anodizing electrolyte 1 litre
- 1 x plastic tray 1 litre
- 2 x graphite electrodes
- 4 x clips
- 1 x 1m titan wire
- 1 x anodised black
- 1 x anodised blue
- 1 x anodised green
- 1 x foam additive
- 1 x pair of goggles
- 1 x pair of gloves

Other versions:
A) + 3-ampere power supply unit
B) + 10-ampere power supply unit
C) + deluxe accessories and 2-ampere power supply unit accessoires "de luxe"
Further needed:

- distilled water (e. g. available at petrol stations)

**Additional options to include in your order:**

- further colours
- many more options --> You will find in our online shop

4. Pre-treatment – mechanical and chemical

4.1 Mechanical pre-treatment

The first step in the anodization process is the mechanic pre-treatment. This is one of the most important steps for the anodization of aluminium because despite of the anodic coating formation every scratch and every imperfection remains visible. Every impurity (grease residue, finger prints etc.) may cause a worse end result. Additionally, the mechanic pre-treatment enables mirror-like aluminium surfaces. It is also important to rinse the work pieces thoroughly in between the individual work steps.

Depending on the condition and state of each surface, different pre-treatment methods are recommended:

- steel wool
- grinding sponge
- brushes
- rotary tools with different attachments
- sand blaster
- polishing paste

There exists no universal strategy for the mechanic pre-treatment: depending on your goal (matt or glossy?), aluminium alloy (hard or soft?) and initial condition (scuffed or already polished), the procedure will vary. But as a general rule, anodization does not (!) compensate for scratches or other imperfections. The quality of the surface before the anodization decides the quality of the end result.
The following table provide an overview concerning the methods for the mechanic pre-treatment, the respectively needed equipment/utensils and subsequently there are illustrations of some tools which are also useful/helpful for the mechanic pre-treatment of aluminium; they may be purchased partially in our online shop, in construction

4.2 Mechanically polishing aluminium to a mirror-like gloss

Below we will describe how aluminium pieces with a mirror-like gloss will also keep this sheen after anodization. All necessary equipment you can purchase in our shop. As an example serves a 50 mm x 20 mm aluminium alloy (EN-AW-5754, also called AlMg3) round blank, which looked before anodization like this:
The surface, dull but otherwise in a good condition, was polished to a high sheen with a molleton wheel, which is an attachment available for conventional drills, by using a polishing paste.

You proceed in the following way: fasten the molleton wheel to the corresponding drill and rub some polishing paste onto the wheel (while this wheel is turning) and rub a bit of the paste also over the object. Then, you polish the object as shown on the following picture:

You see the increasing mirror like gloss come to light. After the polishing, the surface has darkened areas which are easily removed by a cloth and some water.
After this treatment, the round blake looked like this:

But what happens with surfaces which are in a worse condition than the round blank, when they are scratched and worn out? This would also be a case where the molleton wheel with polishing paste is put to use; however, the object has first to be treated with grinding sponge or drill attachments like flap wheels, for example. These can be bought with different corn sizes in construction markets or in online specialist jobs. According to the damages of the surface you have to start out with coarser or finer work. An example for a rather battered surface which we could bring back to a higher gloss after a mechanical treatment is the aluminium kickstand (of an unknown aluminium casting alloy) below, which was afterwards anodized green as well.

The subsequent anodization and dyeing with Tifoo Eloxa-
We are happy to answer any questions to the correct mechanical pre-treatment of aluminium alloys and give recommendations on which tools to choose. We recommend you to send us an email to info@tifoo.de. It is always very helpful if you can include a picture of the object you wish to anodize so that its condition is easier to evaluate.

4.3 Chemical pre-treatment
After the mechanical pre-treatment it is important that the work piece is also treated chemically before the anodization. First rinse the work piece thoroughly with water so that all residue of the mechanical treatment is removed and afterwards immerse it into the Tifoo Anodization activator – because: a completely grease- and dust-free surface is essential for a good anodization result.

The duration of the pre-treatment lasts ca. 5-20 minutes, depending on the degree of soiling. If you wish to check the evenness of the surface during the bath, use tongs to pick the work piece from the bath. If you have achieved the desired result, you should now rinse it thoroughly with distilled water.

The criterion for a well pickled surface: the object stays wet everywhere and the water does not drip off off the surface!

It is important not to touch the aluminium from now on, you should only work with tongs or clean wet gloves to avoid grease spots.
Some alloys (containing Si, Mn or Zn) can cause a dark discolouration of the aluminium.

During the chemical pre-treatment, you should soon observe the formation of gas. If not, this could be a hint to the fact that your aluminium piece is already anodized. You can check by carefully realizing a "scratching test" on a bearly visible part. It's very easy to leave scratch marks on untreated aluminium; if it's anodized, that's more difficult.

If your workpiece is already anodized and you want to remove the oxidation layer, you can use the Tifoo De-Anodizer (available in our online shop).

You can of course also use the De-Anodizer when you yourself have anodized an object but without being satisfied with the result. In this case, you can simply remove the layer and start all over again.

5. Anodic oxidation

The anodic oxidation is the step during which the anodic coating is built up and it is therefore the most important part of the overall process. The schematic assembly of the anodization is seen below:

Choose a suitable container, for example the 1 litre plastic trough of the starter set, and attach the two included graphite electrodes (cathodes) to the two long sides of the trough. This array of two cathodes around the work piece has the merit of a better current density distribution. The aluminium work piece is connected as anode, this means it is connected to the positive pole! Please also mix a
small amount of foam additive into the trough before working, so that a 1 to 2 cm thick foam cover forms.

It is also possible to work with round stainless steel vessels which can function directly as cathodes. But in this case, please always ensure that this kind of stainless steel is indeed resistant to chemicals. For many applications, an amount of 1 to 5 litres of anodization electrolyte should be sufficient. Now the already prepared work piece is fixed in the middle between the electrodes (or respectively in the middle of the stainless steel container). It is important, that all surfaces to be anodized are actually immersed in the liquid.

5.1 Connecting the work pieces to electricity

Titan clamps and wires, which are included in the set, may be used to attach the work pieces. It is important to attach the work pieces in such a way that the contact points do not shift and are firmly attached to each other: if during anodization the titan clamp shifts onto an already anodized, no longer conductive part, the electric current collapses immediately.

The advantages of titan are the resistance against chemical corrosion and which also means that it can be used time and time again. Furthermore, crocodile clips made of stainless steel or nickel-plated steel are also part of the set. These should not come into contact with the anodization electrolytes and are suitable to connect parts to the current, which are not supposed to be anodized completely or to hold the titan clamps in position or else for other connecting assemblies.

You can also make suitable holding or connecting devices out of aluminium. For this, please observe the following instructions: the aluminium rack will logically also be anodized, so this means it has to be pickled. In addition to that, the fixtures should be of the same aluminium alloy as the one which gets anodized. Keep the surface as small as possible, because otherwise high current losses will occur. Generally speaking, position and switch your work pieces always with wet gloves to avoid prints and blemishes.us pouvez aussi faire des installations de contactation ou
5.2 Calculating the current's intensity and the needed time for anodization
The thickness of the anodized layer depends especially on the time of the anodization process and on the current's intensity. A guideline for the intensity to be used is the following rule: 1.5 A per square decimetre (1dm² = 100 cm²) for an anodization period of 60 minutes at room temperature. The current intensity measured in amperes for the corresponding workpiece results from the multiplication of the surface of the measured piece in dm² with 1.5 A.

Surface in dm² x 1.5 A = (surface in cm²)/1000 x 1.5

5.3 Exemplary calculations
An example will make that clearer: An aluminium cylinder / a round rod with a diameter of 2 cm and a height of 10 cm is to be anodized. The cylinder's total surface equals 2 x the base area + shell surface. The shell surface of this cylinder equals to the circumference x the height and therefore equals 63 cm². The cylinder's base area is calculated according to the following formula: (radius)² x pi = 3.1 cm². Therefore results a surface of (2 x 3.1) + 63 = 69.2 ~ 70 cm² (corresponding to 0.7 dm²) for the exemplary cylinder. According to the rule above, our power supply unit should provide a current of

0.7 dm² x 1.5 A = 1.05 A.

As our small power supply unit is capable of providing 2 A, you will be able to anodize at 1.05 A within an hour without any problems. You will also be able to anodize a cylinder with twice the surface with the little power supply unit within an hour. For even bigger objects, you should increase the anodizing time or work with our stronger power supply unit of 10 A (available in our online shop by searching "10 ampere power supply").

Example:
In order to treat an aluminium object with a surface of 200 cm³ = 2 dm², one would need a current strength of 3 A (2 dm² x 1.5 A). So, one needs either a stronger power supply unit or to anodize for 1.5 hours at 2A.
Attention: The other way round, i.e. using a higher current strength in order to anodise for a shorter amount of time and therefore save some time is not recommended because a current density that is too high will destroy the layer.

Please consider the mentioned values to be only guidelines, as the conditions depend on the used alloy, the conductor cross section and on the bath's state. We recommend to work with a current regulation when using our power supply units because the layer's progressing growth increases the electric resistance and the current decreases more and more. When you adjust the corresponding current's intensity on the power supply unit, the latter will regulate the needed tension automatically and you normally shouldn't have to adjust it manually. To do so, first position everything (workpiece, cathodes and the bath) and then, when turned off, you adjust the power supply unit's regulators for the current strength and the voltage completely to zero. Then turn the voltage to the maximum and turn on the device. Now turn the current regulator until the calculated amperage is achieved.

During the anodization, there will be a formation of hydrogen bubbles on the cathode(s). This gas formation is a hint to the fact that the electrochemical reaction works properly.

Please keep in mind that hydrogen and oxygen together form "oxyhydrogen", an explosive and easily available mixture. Even if the quantities are relatively small, you have to guarantee a sufficient ventilation of the anodisation bath and to avoid any fire or ignition source near the corresponding basin.

**Calculation of the layer thickness H:**

H measured in μm = (0.26 x time in minutes x current strength in A) / (surface in dm²)

Example: 
- time = 50 min  
- current strength = 0.3 A  
- surface = 20 cm² = 0.2 dm²  
- H = 19.5 μm
After the desired anodisation time, the power supply unit has to be turned off, the workpiece has to be taken out of the bath and rinsed thoroughly for a long time period first with normal water and afterwards with some distilled water. Better too much than too few of this step! Rinsing too shortly is one of the most frequent reasons for ugly or stained colourations. Please also guarantee to touch the object only by its suspension and to not touch the anodised surfaces. If the object has to be touched despite of that, please only do it with wet rubber gloves.

6. Dyeing
From this point on, dyes can be stored in the pores created by the anodisation. The included dyes are of solid matter. Here are some values to dissolve them in distilled water:

0.1 to 1g per litre --> light colourations
2 to 5g per litre --> strong colourations
> 5g per litre --> dark colourations

You can reuse the dyeing baths several times, but you have to keep the following factors in mind: the pH-value should be between 5.5 et 7.5. If it is too low, please add some NaOH; if it is too high, some acetic acid. It is furthermore important to rinse the workpiece for a sufficient time before dyeing it, as the residues of the anodization electrolyte remaining in the pores can render the dyeing baths ineffective. When a lot of time has passed after the anodization process, it is recommended to dip the aluminium piece again in the anodization electrolyte to "reactivate" the layer. They dye solutions are filled into a heat-resistant receptacle and heated up to 50 to 60 °C. The aluminium piece that just got anodized is rinsed thoroughly and put into the warm dye solution for some minutes. The typical needed time for dyeing with the Tifoo Anodizing colours are from 5 to 20 minutes of effect. If possible, it is advisable to stir during that time so that the bath's circulation is better, which makes the colourations more even. The workpiece is then carefully taken out with a pair of galvanic pliers and rinsed thoroughly.
Important factors to achieve the highest colour authenticity:
- thick oxide layer (< 20 µm)
- well absorbant oxide layers (i.e. anodization at room temperature)
- flawless rinsing after the anodization
- correct concentration of the dye
- long dyeing time guarantees deep colourations (more than 30 minutes however don't have any extra advantage
- perfect sealing (see following chapter)

7. Sealing
Directly after dyeing, the dyed aluminium is put into the already boiling sealing solution. This can e.g. be a special solution for sealing based on heavy metal salt (available in our online shop) or just distilled water (which should especially be exempt from sulphate and phosphate). The sealing causes a hydration of the oxide layer; this means that the pores are closed which seals the surface completely or "locks" the colourants into the layer. Please keep the following mind: the water's or sealing solution's temperature should be of at least 97 °C and the pH-value between 5.5 and 6 (can be tested with paper pH indicator). There is no use sealing for a longer time at a lower temperature - the temperature over 96 °C is decisive! If the pH-value has to be adjusted, please do so with acetic or formic acid - not with sulphuric acid. The time used for the sealing process should be at least 30 minutes.

The ideal time varies according to the layers' thickness. It should be sealed for three minutes per µm, i.e. about 60 minutes for a thickness of 20 µm. Then the colour is firmly bound to the aluminium and the anodization is finished.

The advantage of the sealing solution is that it prevents the non-adhesive dyes from spilling. The colours are therefore stronger and more resistant, but you can also achieve excellent results with distilled water. The distilled water available on here has the advantage that the pH-value is suited (pH 5.5) and already adjusted and stabilized by a buffer system. That's why we recommend you the use of our sealing solutions in order to achieve flawless results.
8. Disposal information

Stick to the instructions of your local waste disposal services or ask them for information about the appropriate disposal.
Short guide

1. Mechanical pre-treatment (grinding, polishing)

2. Rinse

3. Dip in the Tifoo Anodization Activator (5 to 20 minutes, depending on the pollution degree)

4. Rinse

5. Calculate the surface of the aluminium piece to be anodized

6. Position the graphite electrodes inside the basin, dip in the piece you want to anodize for about 45-60 min at 1.5 A/dm², the workpiece is connected to the positive pole and the two graphite sheets to the negative pole.

7. Rinse

8. Dye --> The rinsed workpiece is now dipped in the dyeing bath heated up to 50 °C. Move it around a bit to accelerate the absorption of the dye. The dyeing bath's concentration depends on the dye itself and on the desired saturation. According to the colour's intensity and the bath's concentration, the immersion time is from 2 to 20 minutes. More time in the dyeing bath means a more intense colouration of the workpieces. Thanks to that, you will be able to create light colourations as well as very saturated dyeings very easily - including the different shades between the two.

9. Rinse

10. Seal --> The workpiece is dipped in boiling water for about 60 minutes at at least 96 °C. This closes the pores of the surface and the compound is transformed into its final form responsible for the extreme hardness of the layer.

We recommend distilled water!
